Chirp subbottom profilers

**Principle:** Chirp systems sweep frequency intervals typically in the range 2-20 kHz. Since relatively low frequency/long wavelength signals have better penetration but lower resolution than relatively high frequency/short wavelength signals this allows for an optimal extraction of information from the bottom sediment. Pulse length and type as well as sweeps per second (8 shots per second at 1 knot is optimal for shallow water archaeology) can be adjusted.

**Basic features:** Penetration depth will highly depend on the sediments and improves with increasing depth. It can be up to 50 m into the seabed. Chirp systems have been used successfully to distinguish archaeological features at water depths as shallow as 0.5 m and are especially well suited to distinguish features with a restricted horizontal extension.

**Resolution and horizontal precision:** Resolution down to around 7.5 cm. Separate but adjacent transducers and hydrophones mounted in the ‘fish’ (transducer unit) allows for a higher precision in the horizontal positioning of features observed than if the reflected signal was picked up by a hydrophone array (streamer). A satellite antennae is installed near the fish to obtain a minimal offset. With a DGPS a positioning of observed anomalies a real precision of ± 25 cm can be obtained. This saves diving time when re-locating the anomalies for further investigation.

**Platforms:** Chirp systems can be operated from small vessels. The ‘fish’ (transducer unit) is normally attached to the side of the ship, and only a combined signal processing and recording unit is needed on board.

**Advantages:**
- Very high vertical and horizontal resolution
- Can be operated from very small vessels
- High potential for landscape reconstruction
- Can be used in very shallow water
- Small objects (dm range) can be detected

**Disadvantages:**
- Difficult penetration in hard sandy layers
- 2D image of the subbottom, no 3D
- Problems penetrating sediments with gas
